Abstract

Peyronie's disease is a medical condition characterized by an abnormal curvature of the penis, which presents a poorly understood pathophysiology, featuring abnormal fibroblasts of the tunica albuginea secondary to trauma or stemming from congenital causes. Currently, there are multiple therapeutic options, such as oral pharmacological treatments that either report poor results or partial improvements, as well as intralesional therapies viewed as controversial and surgery as a therapeutic choice. However, this can be implemented once the disease is in its stable phase. A number of alternatives can be elected regarding the needs and symptoms of patients.

Key words: Peyronie's disease. Medical treatment. Surgical treatment.

Introduction

Peyronie's disease (PD) is a connective tissue disease that primarily affects the tunica albuginea of the corpora cavernosa of the penis. François De La Peyronie (1678-1747) first described this disease in a medical treatise addressing ejaculatory failure. It usually presents with a palpable induration of the penis, which causes deformity during erection.

The formation of fibrous plaques in the tunica albuginea and surrounding cavernous tissue alters the anatomy and causes deformities of the penis that is acquired during erection with different degrees of flexion and narrowing of the circumference of the MIMO. This condition can occur with or without pain and can

cause erectile dysfunction. Currently, therapy remains a controversial matter. There is no consensus on the utility of medical and surgical treatment. This article aims to conduct a systemic review of PD and discuss currently available treatments.

Definition

PD is a congenital or acquired penile abnormality, which is characterized by fibrosis of the tunica albuginea¹. The fibrous tissue in the tunica albuginea prevents the expansion of the latter during erection, resulting in shortening, flexion, and pain of the penis, which is associated with sexual dysfunction² (Fig. 1).

Figure 1. Clinical presentation of PD. A ventral defect is observed in the tunica albuginea, causing a pathological curvature of the distal end of the penis.

Pathophysiology

The development mechanism of PD is unknown. However, one of its causes can be due to a prolonged and sustained inflammatory response, triggered by trauma, which allows extravascular protein deposition, inflammatory cell recruitment, fibrin deposition on the expression of inflammatory cytokines, and release of elastase¹, which leads to a change of type I collagen into type III collagen. Overexpression of transforming growth factor (TGF)- β and interleukin (IL)-6 has been reported together with a lower number of blood vessels and reduced apoptosis in the histopathological samples of patients with PD³.

Currently, the active role of free radicals is recognized as inducing an important inflammatory response, favoring the first stage of this disease. There is an important expression of pro-inflammatory and pro-fibrotic cytokines, with subsequent activation of the NF- κ B factor⁴.

Another hypothesis states that it is a scar tissue disorder developed by genetic susceptibility, based on documentary evidence of variations in the TGF- β 1 gene and expression of SMAD transcription factors, which regulate the mechanisms of fibrosis². The histological features of PD show lymphocytic and plasmacytic infiltrate of the tunica albuginea, as well as of the erectile tissues (Fig. 2)³.

Epidemiology

PD mainly affects men aged between 40 and 70 years, mostly of Caucasian origin, with a prevalence of 0.4-9%, and an incidence of 0.39-3%^{3,4}. The risk factor that is majorly associated with PD is trauma. Other associated factors to a lesser extent are peripheral vascular

Figure 2. Peyronie's disease pathophysiology. 1: dorsal vein of the penis, 2: skin, 3: urethra, 4: Buck's fascia, 5: cavernous body, 6: dorsal artery, 7: deep dorsal vein, 8: dorsal nerve of the penis, 9: defect in the tunica albuginea, 10: tunica albuginea, 11: T and B lymphocytes, 12: fibrin deposit, 13: cytosine overexpression, 14: elastase release.

disease, smoking, alcoholism, and some invasive urological procedures (transurethral resection of the prostate and cystoscopy)⁵. Other studies comment on an inverse relationship, with high LDL levels and abdominal circumference, treatment with thiazides and Dupuytren's disease⁴.

Diagnostic approach

A thorough enquiry and physical examination should be performed for a basic evaluation, with an artificially induced erection to measure and document the degree of curvature, as well as document the fibrous plaque by ultrasound scan, if such procedure is available. Patient information should also be collected about the onset of the disease and duration, a history of trauma to the genitals and perineum, the development of penile deformity, curvature, penis shrinkage, erectile dysfunction, and subjective evaluation of the erectile and sexual function².

Clinical presentation

We usually come across patients in their fifties, with a recent onset of curvature in the penis, which is related to mild to moderate pain. The erection is not affected at the beginning. However, the curvature can bring difficulties in sexual activity. It is worth mentioning that abnormalities in the flaccid penis are not palpable¹. During the course of the disease, it can be classified as active and stable.

Table 1. Pharmacological treatment of PD

Pharmaceutical drug	Mechanism of action	Utility
Vitamin E	Reduction of free radicals	No evidence of its utility ¹
Potaba	Inhibits the secretion of glycosaminoglycans	Decreases plaque size, without impact on curvature ^{2,3}
Tamoxifen	Decreases fibrogenesis in the tunica albuginea	No improvement in plaque or curvature ²
Colchicine	Inhibits collagen deposition and decreases TGF-beta 1 expression	Decreases plaque size, without changes in curvature ^{2,3}
Carnitine	Acetyl-CoA carboxylase inhibitor	Reduces pain, curvature, and stops progression ³
L-Arginine	cGMP increase	In animal models, it decreases the size of the fibrous plaque and the expression of type I collagen ²
Pentoxifylline	Nonselective phosphodiesterase inhibitor	Chronic disease improves curvature and plaque volume ²
Corticosteroid	Immune response	No improvement ¹
Collagenase clostridium histolyticum	Interstitial collagen degradation	Decreases curvature, prevents progression ²
Interferon alfa-2b	Inhibits the production of fibroblasts and collagen	reduces plaque size and pain ^{1,14}
Verapamil	Calcium channel blocker	No clinical improvement ²

PD: Peyronie's disease; TGF: transforming growth factor.

Pain or discomfort is reported in the active presentation, with or without an erection, associated with a history of penile injury during sexual activity, although most patients do not remember any incident. The erection may be intact or compromised. The disease stabilizes once no changes in symptomatology are reported within at least 3 months. This generally occurs around 12-18 months after the onset of symptoms. Pain rarely occurs and when it does, it is typically of mild intensity. The plaque is palpable or evident on ultrasound scans with an obvious deformity of the penis¹.

Over time, the penile curvature will get worse in about 30-50% of patients with PD and will stabilize in 47-67% of cases. Pain occurs in about 35-45% of patients at an early stage of the disease and subsides in about 90% of cases at 12 months after the presentation of symptoms⁶. As for findings, comments during medical examinations state that 100% of the patients presented induration, 83% presented induration accompanied by angulation, 46% presented induration accompanied by pain, and only 32% of patients presented induration, angulation, and pain⁷.

Treatment

There are several types of treatment for PD, which must be chosen with moderation and according to the

needs and response of the patient. In general, approaches to treatment should range from less to more invasive ones. Patients with active disease, instability or progression of the deformity should receive conservative treatment, as well as patients with painful erections (particularly on palpation) or those who are not interested in surgical treatment⁸.

Surgical treatment is recommended to those patients who have presented symptoms for at least 12 months or patients whose penile curvature or deformity has become stable for at least 3 months¹. The invasive approach can also be offered to those who have not had a response to medical treatment; patients with unsatisfactory intercourse or those who desire faster results². In its acute phase, nonsteroidal anti-inflammatory drug analgesics are recommended for pain management. Table 1 shows a summary of pharmacological treatment for PD.

Oral treatments

Vitamin E

A fat-soluble vitamin that acts as a natural antioxidant reducing the number of free radicals produced during metabolism. There is no evidence supporting its utility or demonstrating its therapeutic benefit in PD⁹. However, it is frequently prescribed due to its low cost, easy

availability, minimal adverse effects, in addition to its placebo effect¹⁰.

Potaba

Potassium paraminobenzoate has anti-inflammatory and antifibrous properties, inhibiting the secretion of glycosaminoglycans by fibroblasts and stabilizing serotonin monoamine oxidase activity. Several studies have evidenced improvement in plaque size after 12 months, and improvement in pain, without having an effect on pre-existing curvature¹¹.

Tamoxifen

Is an estrogen receptor antagonist whose mechanism of action in the tunica albuginea is the reduction of the fibrogenesis by the modulation of the release of TGF-beta 1. However, it does not generate significant improvement in pain management, penis curvature, or size¹².

Colchicine

It reduces the contraction of wounds and inhibits collagen deposition by decreasing the expression of TGF-beta 1¹³. Some studies comment that it helps in the management of pain in 95% of patient's decreases curvature in 30% of patients¹⁴ and decreases the density of the fibrous plaque in approximately 50% of patients⁶. Other contrast studies reveal that no significant difference has been demonstrated when compared to placebo trials¹⁵.

Carnitine

An Acetyl-CoA carboxylase inhibitor, which has anti-inflammatory properties¹⁶, presents greater benefits compared to tamoxifen in reducing pain, curvature, and stops progression though it does not reduce plaque size⁶.

L-Arginine

A nitric oxide precursor and its anti-inflammatory mechanism is assumed as due to the increase in cGMP. In animal models, it reduces the size of the fibrous plaque and the expression of type I collagen, although no studies have been conducted in humans¹⁷.

Pentoxifylline

Is a non-selective phosphodiesterase inhibitor that restricts fibroblast proliferation, it also contributes by

the diminishment of collagen deposits and elastogenesis¹⁸. It improves curvature and plaque volume in patients with chronic disease¹⁹. It is also believed to stabilize or reduce calcium content in the plaque²⁰.

Intralesional treatment

Corticosteroids

Corticosteroids have an anti-inflammatory effect secondary to suppressing the immune response. Nonetheless, several studies state that it does not present statistically significant evidence for its administration²¹.

Collagenase clostridium histolyticum

Its mechanism of action is through the degradation of interstitial collagen². It should be administered in patients with stable disease and/or curvature between $> 30^\circ$ and $< 90^\circ$ and intact erectile function¹. It reduces penile curvature in patients with the curvature of 30° - 90° , patients who present more than 2 years of evolution, those who do not develop plaque calcification and patients who have an IIEF > 17 . It is thought to reduce sexual activity difficulties in patients with penile curvature ranging from 30° to 60° , disease history of more than 4 years of evolution, non-calcified plaque, IIEF 1-5, and IIEF > 17 ²². Important complications have been reported after the application of this treatment, such as penile hematoma and fracture, detected in up to 10% of patients²³.

IL alpha-2b

IL alpha-2b regulates the immune response, inhibiting the production of fibroblasts and collagen, in addition to increasing collagenase activity. One study reports that it reduces plaque size in 13.5% of patients, and pain in 67.7%¹. Another study reveals that sexual function improves in 30% of patients²⁴.

Verapamil

Is a calcium channel blocker that contributes on the regulation of the inflammatory response and fibroblast proliferation²⁵. However, it does not generate a significant difference with respect to the placebo effect, when plaque size, pain, penile curvature, and sexual function were compared³. One study reports that patients treated with intralesional verapamil for control purposes showed a decrease in plaque size in 17.5% of patients,

pain reduction in 30%, reduced curvature in 17.5%, and improvement in sexual function in 5% of patients. One study states that topical verapamil applied for 9 months decreases penile curvature in 61.1% of participants, with plaque size reduction in 84% of them, pain reduction in 100%, and improvement in the quality perception of erection in 81% of patients²⁶.

Hyaluronic acid

The use of hyaluronic acid has been recently described. Several intra-lesion therapeutic protocols have been proposed for the treatment of PD. A recent study compared the effectiveness of verapamil against hyaluronic acid, stating that the hyaluronic acid group had a greater decrease in curvature and better patient acceptance²⁷.

Non-pharmacologic treatment

Stem cells

Stem cells prevent fibrosis, inducing immunomodulation, which produces phenotypic changes of fibroblasts. Some experiments have been conducted in animal models with induction, where stem cells are applied during its acute phase. These have prevented the development of plaque formation, though there are no studies evidencing its efficacy and safety in humans. Stem cells that have shown greater benefits in animal models are those derived from the adipose tissue. More prospective studies in humans are necessary for a thorough understanding of this therapeutic tool²⁸.

Radiotherapy

Radiotherapy has been used for a long time for PD management because it was thought to help fibrous plaque degeneration. However, all current recommendations contraindicate it²⁹.

Vacuum pump

It presents clinical and statistically significant improvement as PD therapy. Its effectiveness was evaluated in a study where it is commented that 67% of the participants reported a decrease in penile curvature, 10% had an increase in curvature, and 23% of participants did not present any modifications. In addition, 51% of participants declared that they were satisfied with the results, though other participants required

surgical procedures. It is concluded that the vacuum pump improves or stabilizes the curvature of the penis, reducing the need for surgical treatment³⁰.

Extracorporeal shockwave therapy (ESWT)

ESWT is viewed as effective for pain management and improvement of sexual function³¹ but should not be used to reduce curvature or plaque size¹. A study commented that 85% of the participants reported improvement in pain symptoms compared to 48% of participants in the control group. Deviation worsened in 40% of participants and only in 24% of the control group patients. An increase in plaque size was found in 10% of the participants, with no patients in the control group reporting an increase in plaque size³¹.

Surgical treatment

Surgical treatment is aimed to correct penile curvature or deformity, by preserving or restoring erectile function and preventing shrinkage or loss of girth². The most common inclusion criterion for performing the surgical treatment is that 12 months must have elapsed from the onset of symptoms and evidence of stable curvature for at least 3 months⁶. In addition, it can also be offered to those patients who do not have satisfactory intercourse, present failure in conservative treatment and those seeking quicker results⁶.

Some studies comment that conservative treatments of PD are useful for improving pain during erection, but only a small percentage of patients experience penis straightening⁶. There are multiple surgical techniques described for PD correction; however, the most used and most frequently cited are tunical plication, enlargement of the tunica albuginea (incision or excision) and the use of penile prosthesis².

Tunical plication

Tunical plication is the most commonly used technique, representing approximately 50% of all surgeries performed for PD. It is used in patients whose erection is suitable for intercourse or who have erectile dysfunction that responds to medications or vacuum pump¹.

The Nesbit technique is the most commonly used technique, which involves the excision of a portion of the tunica albuginea on the contralateral side of the curvature³². This procedure may result in a decrease in penis size². Studies state that the direction and degree of curvature before surgery predicted this decrease in

penis size³³. A retrospective analysis was conducted in 52 patients undergoing penile plication for the treatment of PD or congenital curvature of the penis. This analysis was compared with techniques that involved degloving or not. Surgical success rates, complications, and patient satisfaction were evaluated with the treatment benefit scale. The overall surgical success rate was 92.3%, with an average follow-up of 18.84 ± 23.51 months. There were no intraoperative complications. In the degloving group, 42.6% of the patients were very satisfied and 42.6% reported better results. In the group that did not undergo degloving procedures, 61.5% of the patients were very satisfied and 30.8% reported better results. The comparison of the results was not statistically significant between the groups³⁴. Currently, this technique is widely used because it is simple, minimally invasive, and preserves sexual function. However, it decreases penis size and does not correct the hourglass defect or hinge effect².

Enlargement of the tunica albuginea

It is used in patients with adequate erection for intercourse and severe deformity (curvature $> 60^\circ$, or articulation with severe plaque calcification)². The most commonly used procedures for tunica albuginea enlargement include partial excision or incision and grafting. Partial excision has displaced complete excision because the latter is greatly associated with erectile dysfunction, and even partial excision can improve sexual function^{35,36}.

The cut is made in the area of maximum curvature, using a double-Y or H incision³⁷. The grafts commonly used are obtained from the dermis, saphenous vein, oral mucosa, proximal crura, tunica vaginalis, dura mater, temporal fascia, and fascia lata³⁸. Synthetic grafts such as Dacron and polytetrafluoroethylene are currently used³⁹. Recent studies comment that this surgical technique helps to straighten the penis in 80-100% of patients. The most frequently encountered complications are hypoesthesia, persistent or recurrent curvature, and erectile dysfunction⁶.

Penile prosthesis

It is used in patients with PD that have erectile dysfunction and/or sufficient deformity to prevent intercourse despite oral medication or vacuum pump¹. It is also used in patients who present a complex deviation that cannot undergo corporoplasty or grafting to improve shrinkage⁴⁰. Two types of prostheses are most

frequently used, malleable prostheses and inflatable prostheses. The most accepted in the management of patients with PD are inflatable prostheses due to better sexual satisfaction for the patient, less residual curvature, and successful straightening⁴¹. An inflatable prosthesis can be used as an effective corrective tool in patients with an unstable penis due to indentation or hourglass deformity and minimal curvature³.

If proper straightening is not achieved with the use of inflatable prostheses, the first step is the manual modeling of the penis². In case of failure of this penile straightening method, the next step is plication, with multiple incisions in the tunica albuginea or excision with or without graft^{39,42}. The most commonly presented complications are penis shrinkage, hypoesthesia, paresthesia, difficulties in inflating and deflating the device, mechanical failure, erosion, and infections⁴³.

Conflicts of interest

The authors have not reported any conflicts of interest.

Ethical disclosures

Protection of human and animal subjects. The authors declare that the procedures followed were in accordance with the regulations of the relevant clinical research ethics committee and with those of the Code of Ethics of the World Medical Association (Declaration of Helsinki).
